1. Intro. This program is an iterative implementation of an interesting recursive algorithm due to Willard L. Eastman, *IEEE Trans.* **IT-11** (1965), 263–267: Given a sequence of nonnegative integers $x = x_0x_1\ldots x_{n-1}$ of odd length n, where x is not equal to any of its cyclic shifts $x_k\ldots x_{n-1}x_0\ldots x_{k-1}$ for $1\le k<n$, we output a cyclic shift σx such that the set of all such σx forms a commafree code of block length n (over an infinite alphabet).

The integers are given as command-line arguments.

The simplest nontrivial example occurs when $n=3$. If $x=abc$, where a, b, and c aren't all equal, then exactly one of the cyclic shifts $y_0y_1y_2=abc$, bca, cab will satisfy $y_0\ge y_1<y_2$, and we choose that one. It's easy to check that the triples chosen in this way are commafree.

Similar constructions are possible when $n=5$ or $n=7$. But the case $n=9$ already gets a bit dicey, and when n is really large it's not at all clear that commafreeness is possible. Eastman's paper resolved a conjecture made by Golomb, Gordon, and Welch in their pioneering paper about comma-free codes (1958).

(Of course, it's not at all clear that we would want to actually *use* a commafree code when n is large; but that's another story, and beside the point. The point is that Eastman discovered a really interesting algorithm.)

Note: This program was written after I presented a lecture about Eastman's algorithm at Stanford on 3 December 2015. While preparing the lecture I realized that some nice structure was present, and a day later it occurred to me that the algorithm could therefore be streamlined. This program significantly simplifies the method of the previous one, which was called COMMAFREE-EASTMAN. It produces essentially the same outputs, but they are reflected left-to-right. (More precisely, if the former program gave the codeword y from the the input sequence $x=x_0\ldots x_{n-1}$, this program gives the reverse of y when given the reverse of x.)

```
#define maxn 105
#include <stdio.h>
#include <stdlib.h>
  int x[maxn + maxn];
  int b[maxn + maxn];
  int bb[maxn];
  ⟨ Subroutines 5 ⟩;
  main(int argc, char *argv[])
  {
    register int i, i0, j, k, n, p, q, t, tt;
    ⟨ Process the command line 2 ⟩;
    ⟨ Do Eastman's algorithm 3 ⟩;
    ⟨ Print the solution 8 ⟩;
  }
```

2. ⟨ Process the command line 2 ⟩ ≡

```
if (argc < 4) {
  fprintf(stderr, "Usage: %s x1 x2 ... xn\n", argv[0]);
  exit(-1);
}
n = argc - 1;
if ((n & 1) ≡ 0) {
  fprintf(stderr, "The number of items, n, should be odd, not %d!\n", n);
  exit(-2);
}
for (j = 1; j < argc; j++) {
  if (sscanf(argv[j], "%d", &x[j - 1]) ≠ 1 ∨ x[j - 1] < 0) {
    fprintf(stderr, "Argument %d should be a nonnegative integer, not `%s'!\n", j, argv[j]);
    exit(-3);
  }
}
```

This code is used in section 1.

3. The algorithm. We think of x as written cyclically, with $x_{n+j} = x_j$ for all $j \ge 0$. The basic idea in the algorithm below is to also think of x as partitioned into $t \le n$ subwords by boundary markers b_j where $0 \le b_0 < b_1 < \cdots < b_{t-1} < n$; then subword y_j is $x_{b_j} x_{b_j+1} \dots x_{b_{j+1}-1}$, for $0 \le j < t$, where $b_t = b_0$. If $t = 1$, there's just one subword, and it's a cyclic shift of x. The number t of subwords during each phase will be odd.

Eastman's algorithm essentially begins with $b_j = j$ for $0 \le j < n$, so that x is partitioned into n subwords of length 1. It successively *removes* boundary points until only one subword is left; that subword is the answer. It operates in phases, so that all subwords during the jth phase have length 3^{j-1} or more; thus at most $\lfloor \log_3 n \rfloor$ phases are needed. (For example, the case $n = 9$ is "dicey" because it might require two phases.)

The algorithm is based on comparison of adjacent subwords y_{j-1} and y_j. If those subwords have the same length, we use lexicographic comparison; otherwise we declare that the longer subword is bigger.

The algorithm is based on an interesting factorization of strings into substrings that have the form $z = z_1 \dots z_k$ where $k \ge 2$ and $z_1 \ge \cdots \ge z_{k-1} < z_k$. Let's call such a substring a "dip." It is not difficult to see that any string $y = y_0 y_1 \dots$ in which the condition $y_i < y_{i+1}$ occurs infinitely often can be factored *uniquely* as a sequence of dips, $y = z^{(0)} z^{(1)} \dots$. For example, $3141592653589\ldots = 314\,15\,926\,535\,89\ldots$.

Furthermore if y is a periodic sequence, its factorization is also ultimately periodic, although some of its initial factors may not occur in the period. Consider, for example, the factorizations

$$1234501234501234501\ldots = 12\,34\,501\,23\,45\,01\,23\,45\,01\ldots;$$
$$12345601234560123456601\ldots = 12\,34\,56\,01\,23\,45\,601\,23\,45\,601\ldots.$$

If the period length is t, and if i_0 is the smallest i such that $y_{i-3} \ge y_{i-2} < y_{i-1}$, then one of the factors ends at i_0 and all factors are periodic after that point. The value of i_0 is at most $t + 2$.

Since t is odd, the period contains an odd number of dips of odd length. Each phase of Eastman's algorithm simply retains the boundary points that precede those odd dips.

⟨ Do Eastman's algorithm 3 ⟩ ≡
```
⟨ Initialize 4 ⟩;
for (p = 1, t = n; t > 1; t = tt, p++)
  ⟨ Do one phase of Eastman's algorithm, putting tt boundary points into bb 6 ⟩;
```
This code is used in section 1.

4. We might need to refer to $b[n + n - 1]$, but not $b[n + n]$.

⟨ Initialize 4 ⟩ ≡
```
for (j = n; j < n + n; j++) x[j] = x[j − n];
for (j = 0; j < n + n; j++) b[j] = j;
t = n;
```
This code is used in section 3.

5. Here's a basic subroutine that returns 1 if subword y_{i-1} is less than subword y_i, otherwise it returns 0.

```
⟨ Subroutines 5 ⟩ ≡
  int less(register int i)
  {
    register int j;
    if (b[i] − b[i − 1] ≡ b[i + 1] − b[i]) {
      for (j = 0; b[i] + j < b[i + 1]; j++) {
        if (x[b[i − 1] + j] ≡ x[b[i] + j]) continue;
        return (x[b[i − 1] + j] < x[b[i] + j]);
      }
      return 0;      /* y_{i−1} = y_i */
    }
    return (b[i] − b[i − 1] < b[i + 1] − b[i]);
  }
```

This code is used in section 1.

6.

```
⟨ Do one phase of Eastman's algorithm, putting tt boundary points into bb 6 ⟩ ≡
  {
    for (i = 1; ; i++)
      if (¬less(i)) break;      /* now i ≤ t and y[i − 1] ≥ y[i] */
    for (i += 2; i ≤ t + 2; i++)
      if (less(i − 1)) break;
    if (i > t + 2) {
      fprintf(stderr, "The␣input␣is␣cyclic!\n");
      exit(−666);
    }      /* now y[i − 3] ≥ y[i − 2] < y[i − 1] */
    if (i < t) i0 = i; else i = i0 = i − t;
    for (tt = 0; i < i0 + t; i = j) {
      for (j = i + 2; ; j++)
        if (less(j − 1)) break;      /* advance past the next dip */
      if ((j − i) & 1) ⟨ Retain i as a boundary point 7 ⟩;
    }
    printf("Phase␣%d␣leaves", p);
    for (k = 0; k < tt; k++) b[k] = bb[k], printf("␣%d", bb[k]);
    printf("\n");
    for ( ; b[k − tt] < n + n; k++) b[k] = b[k − tt] + n;
  }
```

This code is used in section 3.

7. If $i \geq t$ at this point, we have "wrapped around," so we actually want to retain the boundary point $i-t$. (This case will arise at most once per phase, because $j \geq i+3$ and we must have $j = i0 + t$. Therefore $i - t$ will be smaller than all of the previously retained points, and we want to shift them one space to the right.)

```
⟨ Retain i as a boundary point 7 ⟩ ≡
  {
    if (i < t) bb[tt++] = b[i];
    else {
      for (k = tt++; k > 0; k−−) bb[k] = bb[k − 1];
      bb[0] = b[i − t];
    }
  }
```

This code is used in section 6.

8. ⟨ Print the solution 8 ⟩ ≡

```
for (j = b[0]; j < b[0] + n; j++) printf("␣%d", x[j]);
printf("\n");
```

This code is used in section 1.
